ABSTRACT

We study the three-dimensional and projected shapes of galaxy groups in the Sloan Digital Sky Survey Data Release 4, and examine the alignment between the orientation of the central galaxy and the spatial distribution of satellite galaxies. The projected ellipticity of a group is measured using the moments of the discrete distribution of its member galaxies. We infer the three-dimensional and projected axis ratios of their dark matter haloes by comparing the measured ellipticity distributions with those obtained from Monte Carlo simulations of projected, triaxial dark matter haloes with different axis ratios. We find that the halo shape has a strong dependence on the halo mass. While the haloes of low-mass groups are nearly spherical, those of massive groups tend to be prolate. For groups containing at least four members, the statistical distribution of their measured ellipticities does not have a strong dependence on the colors of their central galaxies. Our analysis further shows that the average three-dimensional axis ratio for haloes with $12 < \log[M/(h^{-1}M_{\odot})] \leq 15$ is about 1 : 0.46 : 0.46, resulting in a projected axis ratio of ~ 0.77 . Our results for the alignment between the orientation of the central galaxy of a group and the distribution of their satellite galaxies are in broad agreement with those obtained by Yang et al. The distribution of satellite galaxies preferentially aligns with the major axis of the central galaxy, with a clear dependence on both halo mass and galaxy colors. In particular, the alignment is stronger in more massive groups, and the strongest alignment is seen between red centrals and the distribution of red satellites. For groups with blue centrals, no significant alignment is detected. Finally, we examine how the observed alignment can be reproduced with the information about the halo axis ratios. The observed alignment signal can be reproduced if the angle between the major axis of the central galaxy and the projected major axis of the host halo has a Gaussian distribution with a mean of 0° and a dispersion of $\sim 23^\circ$. This dispersion is larger for groups with blue centrals than those with red centrals.

1 INTRODUCTION

In the cold dark matter scenario, small dark matter haloes form first and grow subsequently to larger structures via ac-

cretion and merging processes. Such processes are generally anisotropic so that dark matter haloes are expected to be non-spherical. The orientations of dark matter haloes can be related to their surrounding structures, such as filaments and large-scale walls (e.g., Faltenbacher et al. 2002; Einasto et al. 2003; Avila-Reese et al. 2005; Hopkins, Bahcall & Bode

* E-mail: wangyg@bao.ac.cn

2005; Kasun & Evard 2005; Basilakos et al. 2006; Altay et al. 2006; Aragon-Calvo et al. 2006; Maulbetsch et al. 2007; Ragone-Figueroa & Plionis 2007; Hahn et al. 2007a, 2007b). The last major merger of a dark matter halo may play an important role in determining its shape (van Haarlem & van de Weygaert 1993), although interactions between the gas and the dark matter components are also expected to play a role (Kazantzidis et al. 2004). Thus the shapes and orientations of dark matter haloes contain abundant information about their formation histories, which, in turn depend on the underlying cosmology (Lee 2006; Ho et al. 2006). On the other hand, the non-sphericity of dark matter haloes can also lead to systematic errors in cosmological studies (Sulkkanen 1999; Wang & Fan 2006). Therefore it is of great importance to characterize the shapes of dark matter haloes, both observationally and theoretically.

The shapes of clusters of galaxies can be probed using X-ray observations, studies of the Sunyaev-Zeldovich effect, and gravitational lensing (e.g., Zaroubi et al. 1998, 2001; Relinsky 2000; Lee & Suto 2004; Wang & Fan 2004; De Filippis et al. 2005; Sereno et al. 2006). However, one can also use the spatial distribution of satellite galaxies, since these are expected to be good tracers of the shapes of their host haloes. The large redshift surveys carried out in recent years, for example, the two-degree Field Galaxy redshift Survey (2dFGRS) and Sloan Digital Sky Survey (SDSS), have provided angular positions and redshifts for hundreds of thousands of galaxies, which allow detailed studies of the shapes of large samples and the shape dependence on richness, multiplicity and dynamical evolution of groups and clusters. Early studies preferred the prolate shapes (Carter & Metcalfe 1980; Binggeli 1980; Plionis, Barrow & Frenk 1991; Fasano et al. 1993; Cooray 2000; Basilakos, Plionis & Maddox 2000; Orlov, Petrova & Martynova 2001), but did not exclude the oblate solutions. Plionis et al. (2004) (hereafter P04) estimated the shape distribution of UZC-SSRS2 groups of galaxies by analyzing the spatial distribution of group members. They found that the prolate-like shape fits very well the cosmic structure on a large scale apart from the disc galaxy. Somewhat surprisingly, they also found that poor groups are more elongated than rich ones, results which are opposite to what is found in numerical simulations (eg., Allgood et al. 2006; Kasun & Evrard 2005).

Somewhat surprisingly, these results are opposite to what is found with numerical simulations (Allgood et al. 2006; Kasun & Evrard 2005). Recently, they estimated the average group morphology of the Percolation-Inferred Galaxy Group (2PIGG) and found that the prolate or, triaxial with pronounced prolate shapes are the only acceptable morphological model (Plionis et al. 2006).

In this paper, we use data from the SDSS to study the shapes of galaxy groups, under the assumption that the spatial distribution of group members traces the matter distributions of their underlying dark matter haloes. Differing from previous studies, we run Monte Carlo simulations to generate the same number of member galaxies as in each of the observed groups under the assumption that haloes of the groups follow the triaxial model of Jing & Suto (2002) (hereafter JS02). We then make 2D projected distributions of these member galaxies, which serve as our Monte Carlo mock samples. We compare the ellipticity distribution ob-

tained from the mock sample with the observed one to extract information on the axis ratios of dark matter haloes.

In the second part of this paper we revisit the alignment between the spatial distribution of satellite galaxies in groups and the orientation of their central galaxies (hereafter ‘centrals’). It is important to assess accurately the alignment of the dark matter halo because it holds important clues regarding the actual assembly history of dark matter haloes. Extensive studies with high resolution simulations have shown dark matter haloes have anisotropic distributions of subhaloes that are aligned with their major axis (Knebe et al. 2004; Libeskind et al. 2005; Wang et al. 2005; Zentner et al. 2005). This anisotropy mainly owes to a preferred direction of satellite accretion along large-scale filaments (Tormen 1997; Vitvitska et al. 2002; Aubert, Pichon & Colombi 2004; Knebe et al. 2004; Wang et al. 2005; Zentner et al. 2005). In addition, the tidal forces from the host halo may also induce new alignments (e.g., Ciotti & Dutta 1994; Usami & Fujimoto 1997; Fleck & Kuhn 2003; Wang et al. 2007). Conversely, some nonlinear effects such as violent relaxation and encounters can weaken the primordial alignment (e.g., Porciani et al. 2002).

Comparing with the simulation studies, the observational search for a possible alignment of central galaxies and their satellites has a long and confusing history. The first study of such an alignment was by Holmberg (1969), who found that satellites are preferentially located along the minor axes of isolated disc galaxies. Holmberg’s study was restricted to projected satellite-central distances of $r_p \lesssim 50$ kpc. Subsequent studies, however, were unable to confirm this so-called ‘Holmberg effect’ (Hawley & Peebles 1975; Sharp, Lin & White 1979; MacGillivray et al. 1982). Zaritsky et al. (1997) studied the distribution of satellites around spiral hosts and were also unable to detect any significant alignment for $r_p \lesssim 200$ kpc, but they found a preferred minor-axis alignment for $300 \text{ kpc} \lesssim r_p \lesssim 500 \text{ kpc}$. Our Milk Way and M31 have satellites that lie in great planes that are highly inclined to their discs (Lynden-Bell 1976, 1982; Majewski 1994; Hartwick 1996, 2000; Kroupa et al. 2005; Koch & Grebel 2006; McConnachie & Irwin 2006; Metz et al. 2007). With large redshift surveys, such as 2dFGRS and SDSS, much larger samples of galaxy groups can be used to discuss the alignment problem. Sales & Lambas (2004) used a set of 1498 host galaxies with 3079 satellites from the 2dFGRS and found a large-scale (alignment of the satellites along the host minor axes for $300 \text{ kpc} \lesssim r_p \lesssim 500 \text{ kpc}$. Brainerd (2005) studied a sample of isolated SDSS galaxies and found that the distribution of satellite galaxies is strongly aligned with the major axis of the disc host galaxy. Yang et al. (2006, hereafter Y06), using a galaxy group catalogue similar to the one used here, but based on the SDSS Data Release 2 (DR2), studied the alignment signal as function of the colors of the central and satellite galaxies. They found that the alignment strength is strongest between red centrals and red satellites, while the satellite distribution in systems with a blue central galaxy is consistent with being isotropic. Y06 also found that the alignment strength is stronger in more massive haloes and at smaller projected radii from the central galaxy. These results have subsequently been confirmed by several independent studies (Donoso, O’Mill & Lambas 2006; Azzaro et al. 2007; Agustsson & Brainerd 2006a, 2007). Using the same group catalogue as that

used here, Faltenbacher et al. (2007a) examined several additional alignment signals. They found that the orientations of red satellites are preferentially aligned radially in the direction of the brightest group galaxies (BGG). In addition, they found a weak but significant indication that the orientations of satellite galaxies are directly aligned with that of their BGG. Comparing with the earlier studies of the alignment between brightest cluster galaxies (BCGs) and their parent clusters (Carter & Metcalfe 1980; Binggeli 1982; Struble 1990; West 1994; Kim et al. 2001), Faltenbacher et al. (2007a) have given more detailed results for the large samples. These various detections of alignment between centrals and satellites have triggered a number of investigations into the connection between the shapes and orientations of dark matter haloes and their galaxy population, with the goal to improve our understanding of the formation of dark matter haloes and galaxies (e.g. Agustsson & Brainerd 2006b, hereafter, AB06; Kang et al. 2007, hereafter K07; Faltenbacher et al. 2007b; Brunino et al. 2007; Sales et al. 2007; Pereira et al. 2007).

In addition to measuring the alignment signals from the SDSS observations for groups of different masses, we try to infer the correlation between the orientations of the central galaxy and that of its host halo, statistically but both from the observations. If the projected orientation of a central galaxy is perfectly aligned with the projected orientation of its host dark matter halo, assuming that satellite galaxies trace the matter distribution, the alignment signal between the distribution of satellite galaxies and the orientation of their central galaxy is strongest. By comparing the alignment signals measured from the observations and the Monte Carlo samples, we can estimate the deviation (misalignment angle) of the orientation of central galaxy from the orientation of its host dark matter halo. We use a Gaussian distribution function to quantify this misalignment angle.

This paper is organized as follows. In §2, we briefly describe the observational data used for this study. Section 3 presents our measurements of the intrinsic shapes of dark matter haloes, where the three-dimensional and two-dimensional axis ratios are determined using Monte Carlo simulations. Section 4 shows the alignment signal we measured from the SDSS and its implication for the shape correlation between the central galaxies and the dark matter haloes. Finally, §5 presents a summary and discussion. Throughout this paper we refer to the inferred shape from the satellite galaxy distribution as the shape of the group and the corresponding dark matter halo, and use the major-axis direction of the satellite distribution to indicate the orientation of the group and the corresponding dark matter halo.

2 DATA

The analysis presented in this paper is based on the SDSS DR4 galaxy group catalogue of Yang et al. (2007). This group catalogue is constructed applying the halo-based group finder of Yang et al. (2005a) to the New York University Value-Added Galaxy Catalogue (NYU-VAGC; see Blanton et al. 2005), which is based on SDSS DR4 (Adelman-McCarthy et al. 2006). From this catalogue Yang et al. selected all galaxies in the Main Galaxy Sample with redshifts

in the range $0.01 \leq z \leq 0.20$ and with a redshift completeness $\mathcal{C} > 0.7$. This sample of galaxies is used to construct three group samples: sample I, which only uses the 362356 galaxies with measured redshifts from the SDSS, sample II which also includes 7091 galaxies with SDSS photometry but with redshifts taken from alternative surveys, and sample III which includes an additional 38672 galaxies that lack a redshift due to fiber-collisions, but which we assign the redshift of its nearest neighbor (cf. Zehavi et al. 2002). The present analysis is based on sample II which consists of 369447 galaxies distributed over 301237 groups with a sky coverage of 4514 deg^2 . Details of the group finder and the general properties of the groups can be found in Yang et al. (2007).

In this paper, the central galaxy is defined to be the brightest galaxy in the group and other galaxies are satellites. We also take the most massive (in terms of stellar mass) group member as the central galaxy. As we have tested, the difference between these two definitions is too small to be noticed. The group masses are estimated using the ranking of group's characteristic luminosity, $L_{19.5}$, defined as the combined luminosity of all group members with $^{0.1}M_r - 5 \log h \leq -19.5$. More details of the mass estimations can be found in Yang et al. (2007). Note that, the selected galaxy groups contain a small fraction of interlopers, i.e. false members assigned to a group. If the distribution of these interlopers is uncorrelated (or anti-correlated) with that of the true members of the group, our results on both the ellipticity and the alignment can be biased. According to Yang et al. (2007; 2005a) the average fraction of interlopers in the group is less than 20%. We have tested the effect of such fraction by assuming that the distribution of the interlopers is uncorrelated with the shape of the group and is spherical, we find that the presence of the interlopers can decrease the ellipticity of the groups and the alignment signals by $\sim 10\%$.

Note that in these group catalogues survey edge effects have been taken into account (Yang et al. 2007). Only groups with $f_{\text{edge}} \geq 0.6$ are selected, where $1 - f_{\text{edge}}$ is the fraction of galaxies in a group that are missed due to the edge effects. In order to obtain the ellipticity distribution of galaxy groups, we only use groups with at least four members (one central galaxy and at least three satellites), which results in a catalogue of 5184 groups. However, in studying the alignment between satellite galaxies and the orientation of their centrals, we enlarge our sample by using all groups with at least two members (one central and one satellite). This sample gives a total of 62212 unique central-satellite pairs, many more than in the DR2 sample used by Y06.

3 THE INTRINSIC SHAPE OF THE DARK MATTER HALO

3.1 Methodology

We now describe how we use the satellite distribution to determine the ellipticity distribution of galaxy groups and their corresponding dark matter haloes. The observed satellite distribution in a group suffers from severe discreteness effects. In particular, since each group contains only a small number of galaxies, there is a high level of Poisson noise in

the determination of the ellipticity based on its galaxy distribution. Thus the ellipticity directly measured can only be used as a rough indicator of the underlying, true ellipticity. We will use mock samples to quantify how the observed ellipticity distribution is related to the real distribution. Assuming that the distribution of satellite galaxies in a group traces the mass distribution in the corresponding dark matter halo, we can infer, in a statistical sense, the shapes of dark matter haloes from the observed distribution of the group ellipticities. In order to obtain the principal axes and the orientation of a group projected on the sky, we define the inertia tensor as

$$X_{ij} = \sum_{i=1}^n x_{i,n} x_{j,n} \quad (1)$$

where $(x_{i,n}, x_{j,n})$ are the projected coordinates (with the central galaxy at the origin) of the n^{th} satellite galaxy. The semi-major and semi-minor axes of the ellipse, L_a and L_b (two roots of the following equation), can be derived by solving the equation

$$\begin{vmatrix} X_{11} - L^2 & X_{12} \\ X_{12} & X_{22} - L^2 \end{vmatrix} = 0 \quad (2)$$

The direction of the major axis is given by the eigenvector $\mathbf{r} = [1, (L_a^2 - X_{11})/X_{12}]$, while the ellipticity, ϵ , and the axis ratio, η , are

$$\epsilon = 1 - L_b/L_a, \quad \text{and} \quad \eta = L_b/L_a. \quad (3)$$

Throughout this paper, we use the ellipticity ϵ and axis ratio η to refer to the quantities *measured directly* from the data. The inferred shapes of the underlying dark matter haloes are described either by their 2D or 3D axis ratios.

As mentioned above, to quantify the true shapes of the dark matter haloes associated with the galaxy groups, one needs to construct mock samples that include the same selection effects. We construct Monte Carlo SDSS DR4 group catalogues as follows. First, we determine the number of satellites for each of the SDSS groups. Second, we re-distribute these satellites according to a spherical NFW profile (Navarro et al. 1996, 1997) or a triaxial profile by JS02. Third, we project the three dimensional distribution of satellite galaxies onto a two dimensional plane and measure the ellipticity, ϵ_{MC} , for each Monte-Carlo group. Such Monte Carlo approach was firstly introduced by Basilakos, Plionis & Maddox (2000) to recover the projected cluster ellipticity distribution and the true projected ellipticity distribution taking into account the background and discreteness effects (see also Plionis et al. 2006). Thirty Monte-Carlo realizations are generated, and we estimate the average and scatter of the ellipticity distribution using these thirty Monte Carlo samples. Some small groups with masses smaller than $10^{11.6} h^{-1} M_\odot$, where SDSS DR4 group catalogue does not provide mass estimates, are removed from our sample.

The first model for the mass profile used in our Monte Carlo simulations is a spherical NFW density profile,

$$\rho_{\text{NFW}}(r) = \frac{\rho_0 \delta_c}{(r/r_s)(1 + r/r_s)^2} \quad (4)$$

where ρ_0 is the average mass density of the universe, r_s is a scale radius and $\delta_c = 200c^3/3[\ln(1+c) - c/(1+c)]$. The concentration parameter c is defined as $c = r_{200}/r_s$, with r_{200} the radius within which the mean density is 200 times

the average mass density of the universe. This model is fully determined for a halo of a given mass (or, equivalently, r_{200}) once the concentration parameter is given. The concentration parameter depends on the halo mass M and redshift z , for which we use the model of Bullock et al. (2001):

$$c(M, z) = \frac{c_\star}{1+z} \left(\frac{M}{10^{14} h^{-1} M_\odot} \right)^{-0.13}, \quad (5)$$

where $c_\star = 8$, as is appropriate for the Λ CDM model.

The other density profile we use is that proposed by JS02. Using high-resolution numerical simulations, JS02 proposed an NFW-like triaxial density profile for dark matter haloes, which has the form

$$\rho(R)_{\text{JS02}} = \frac{\rho_0 \delta_c}{(R/R_0)^\alpha (1 + R/R_0)^{3-\alpha}}, \quad (6)$$

where $R = a(x^2/a^2 + y^2/b^2 + z^2/c^2)^{1/2}$, and $a \geq b \geq c$ are the lengths of the three principal semi-axes. For the value of α , it is found that both $\alpha = 1$ and 1.5 can provide a good fit to the simulated profiles. Detailed comparisons showed that $\alpha = 1$ is slightly better for cluster-scale haloes, while $\alpha = 1.5$ gives better fit for galactic haloes (JS02). Therefore, we adopt $\alpha = 1.5$ for groups with masses smaller than $10^{13} h^{-1} M_\odot$, and $\alpha = 1.0$ for more massive groups (In fact, the results are not sensitive to the value of α adopted. We have also adopted $\alpha = 1.0$ for all groups, their differences are tiny.).

3.2 Ellipticity distribution

Figs. 1 and 2 show the probability distributions of the ellipticity obtained from the SDSS DR4 (dotted histogram) and from the Monte Carlo simulations (solid histogram with error bars). In Fig. 1, we assume that the distribution of satellite galaxies follows a spherical NFW profile, while in Fig. 2 we assume that the distribution of satellite galaxies follows the JS02 model. For the JS02 triaxial distribution, we have adopted the model parameters (axis ratios and concentrations) given in JS02. In both cases we randomly select a line-of-sight direction, project the three-dimensional satellite distribution onto a two-dimensional plane, and measure the ellipticity distribution using the method outlined above. In each plot, the parameter N represents the lower limit on the number of galaxies in each group (including the central galaxy). Note that the ellipticity distribution is strongly dependent on this lower limit, with poorer groups being more elongated. The mean ellipticity increases from ~ 0.40 for groups with richness $N \geq 10$ to ~ 0.54 for groups with $N \geq 4$. However, this does not mean that the true halo shape is more elongated for poorer groups; the trend is largely a result of the discrete sampling. For example, in the extreme case where only one satellite galaxy is observed, the measured ellipticity will always be unity regardless of the shape of the underlying dark matter halo. Thus, the shape of the underlying halo shape can only be probed in an indirect way, i.e., by comparing the observed distribution with that of the Monte-Carlo samples.

From Fig. 1 and 2, it appears that the triaxial model of JS02 fits the data better relative to the spherical NFW model.

Figure 1. Probability distributions of the ellipticity in the SDSS DR4 (dotted histogram) and Monte Carlo re-samplings (solid histogram with error bars). Here we assume that the distribution of satellite galaxies in groups follows a spherical NFW profile.

Figure 2. Same as Fig. 1, but here we assume that the satellite galaxies are distributed in groups according to JS02 triaxial model.

3.3 The three-dimensional and projected shapes of dark matter haloes

Numerous studies have used numerical N -body simulations to probe the non-spherical shapes of dark matter haloes as traced by dark matter particles (e.g., JS02; Kazantzidis et al. 2004), or by subhaloes (e.g., Diemand, Moore & Stadel 2004). The subhaloes are more closely associated with satellite galaxies, which have been found to be biased tracers of the mass distribution. There is a negative spatial bias at the center, and a corresponding positive velocity bias. It is still unclear whether this reflects numerical artefact (i.e., over-merging), or whether this is real. Yang et al. (2005b) studied the satellite distributions in the 2dFGRS groups and found evidence that the number density distribution of satellites is less concentrated than expected dark matter. Here we probe the mean values of axis ratios of dark matter haloes as traced by SDSS galaxies. For this purpose, we first divide the SDSS DR4 groups into subsamples according to their halo masses, and measure the corresponding ellipticity dis-

Table 1. Best-fit parameters for groups in different halo mass bins. From top to bottom, values are listed for groups with different members $N \geq 4, 6, 8$, and 10, respectively.

Mass bin	3D axis ratios (I)	χ^2 (I)	2D axis ratios (II)	χ^2 (II)
$12 < M' \leq 13^a$	1:0.96:0.85	22.58	$0.96^{+0.01}_{-0.02}$	46.16
$13 < M' \leq 14$	1:0.80:0.72	29.93	$0.83^{+0.02}_{-0.01}$	28.30
$14 < M' \leq 15$	1:0.88:0.44	11.86	$0.69^{+0.01}_{-0.01}$	19.13
$12 < M' \leq 15$	1:0.46:0.46	67.63	$0.77^{+0.03}_{-0.01}$	56.02
$12 < M' \leq 13$	1:0.96:0.95	12.47	$0.86^{+0.02}_{-0.04}$	20.49
$13 < M' \leq 14$	1:0.96:0.63	10.75	$0.76^{+0.01}_{-0.01}$	16.29
$14 < M' \leq 15$	1:0.35:0.35	17.78	$0.68^{+0.01}_{-0.01}$	52.10
$12 < M' \leq 15$	1:0.51:0.48	13.17	$0.72^{+0.01}_{-0.01}$	14.63
$12 < M' \leq 13^b$	—	—	—	—
$13 < M' \leq 14$	1:0.87:0.53	5.36	$0.72^{+0.01}_{-0.01}$	10.40
$14 < M' \leq 15$	1:0.33:0.33	33.19	$0.70^{+0.01}_{-0.02}$	89.14
$12 < M' \leq 15$	1:0.43:0.43	17.05	$0.72^{+0.01}_{-0.01}$	29.53
$12 < M' \leq 13$	—	—	—	—
$13 < M' \leq 14$	1:0.84:0.50	7.68	$0.72^{+0.01}_{-0.01}$	12.63
$14 < M' \leq 15$	1:0.61:0.36	34.84	$0.68^{+0.01}_{-0.01}$	60.24
$12 < M' \leq 15$	1:0.39:0.39	23.04	$0.71^{+0.01}_{-0.01}$	48.66

^a $M' = \log[M/(h^{-1} M_\odot)]$.

^b The axis ratios in the $12 < M' \leq 13$ mass bin with $N \geq 8$ and $N \geq 10$ are absent because our group sample contains too few of these rich groups for a reliable measurement of the ellipticity distribution.

tribution as traced by the satellite galaxies. Then, using the model of JS02 with given axis ratios, we construct thirty realizations of Monte Carlo simulations and measure the corresponding ellipticity distributions. By changing model parameters (i.e. axis ratios) so that the predicted ellipticity distributions match the observed one, we determine the underlying axis ratios of dark matter haloes. Here the comparison between model predictions and observation is done in terms of a χ^2 , defined as

$$\chi^2 = \sum_{i=1}^{N_b} \frac{(\langle f_{i(MC)} \rangle - f_{i(obs)})^2}{\sigma^2(f_{i(MC)})} \quad (7)$$

where $N_b = 10$ denotes the bin number of the ellipticity distribution. $\langle f_{i(MC)} \rangle$ and $\sigma^2(f_{i(MC)})$ are, respectively, the average amplitude and 1- σ deviation of the ellipticity distributions obtained from the thirty realizations of Monte Carlo simulations, while $f_{i(obs)}$ is the amplitude of the ellipticity distribution obtained from the SDSS groups. Note that for each set of axis ratios, $\sigma^2(f_{i(MC)})$ changes slightly. However, as we have tested, using constant $\sigma^2(f_{i(MC)})$ does not have a significant impact on our measurement of the best-fit axis ratios. Thus we use $\sigma^2(f_{i(MC)})$ computed from the thirty Monte Carlo simulations and estimate the best-fit axial ratios by minimizing the χ^2 . Here the minimization is performed on the regular 100×100 (3D) or 100 (2D) axis ratio grids.

In Fig. 3 we compare the ellipticity distribution for groups in different mass bins (dotted histograms) with those of the best-fit Monte-Carlo simulation (solid histograms with errorbars). The corresponding best-fit, three-dimensional (3D) axis ratios for the dark matter haloes are

Figure 3. Similar to Fig. 1, but for groups in different mass bins as indicated on top of the panels. In this plot, the Monte Carlo simulations are performed according to the JS02 profile with the best-fit three-dimensional axis ratios. The line-of-sight (projection) direction is random.

listed in the second column of Table 1. As one can see, the 3D axis ratios recovered are different for groups with different richness. The results indicate that less massive haloes are more spherical, while more massive haloes tend to be more prolate. These results are in good agreement with Paz et al. (2006; hereafter P06), who studied the shapes of dark matter haloes, both projected and in 3D, using simulations and groups constructed from the 2-degree Field Galaxy Redshift Survey (2dFGRS; Colless et al. 2001) and the SDSS DR3.

In addition to the three-dimensional axis ratios, we can also look into the projected two-dimensional (2D) axis ratios. Assuming a projected major-to-minor axis ratio, we re-sample the sky positions of satellite galaxies in each group in a Monte Carlo way, and measure the corresponding ellipticity distribution for groups of different masses and richness. Here again, by changing the 2D axis ratio, we can obtain the one that best matches the observed ellipticity distribution of groups. The results are shown in Fig. 4, and the corresponding best-fit, 2D axis ratios are listed in the fourth column of Table 1. Once again less massive groups are found to be more spherical. Note that groups in the same mass bin, but with different richness, have only slightly different 2D axis ratios.

The χ^2 values presented in Table 1 for the best fit models are quite large, especially for groups with halo masses

$10^{12} - 10^{15} h^{-1} M_{\odot}$ in the 3D cases, and in a few 2D cases. Possible reasons for such large χ^2 are (i) the assumption of a constant axis ratio is not accurate to describe the shape of the groups, and (ii) the shapes of observed groups do not follow a Gaussian distribution. Unfortunately, without better knowledge about these issues, it is difficult to come up with a better model.

Observationally, only gravitational lensing data can directly probe the 2D, projected mass distribution of dark matter haloes. However, at the present time, such observations are limited in both quality and quantity (see Hoekstra et al. 2004; Mandelbaum et al. 2006). For clusters of galaxies, additional data is available from X-ray data and from studies of the Sunyaev-Zeldovich-effect. These data yield constraints on the shapes of cluster haloes from their gas distribution. Mohr et al. (1995) used a sample of 57 X-ray clusters observed by the Einstein telescope and obtained a mean 2D axis ratio, $\langle \eta \rangle = 0.80$, and a dispersion $\sigma_{\eta} = 0.12$. With the JS02 model, Wang & Fan (2004) studied the Sunyaev-Zeldovich effect and X-ray surface brightness profiles for clusters of galaxies. Based on a sample of clusters with masses above $M_{\text{lim}} = 10^{14} h^{-1} M_{\odot}$, they found that the average axis ratios is $\langle \eta \rangle \sim 0.84$. Sereno et al. (2006) used a sample of 25 X-ray selected clusters observed by *Chan-*

Figure 4. Similar to Fig. 3, but for the best-fit two-dimensional axis ratios.

dra and *XMM-Newton*, and obtained a mean projected axis ratio $\langle \eta \rangle = 0.80 \pm 0.02$. Recently, Flores et al. (2007) predicted that the mean axis ratio is $\langle \eta \rangle = 0.82$ and a scatter $\sigma_\eta = 0.09$ using a simple analytical model. Note, though, that all these measurements are for the axis ratios of the hot intra-cluster gas. Lee & Suto (2003) presented an analytical expression that links the ellipticity of the gas to that of the dark matter halo, assuming that the intra-cluster gas is in hydrostatic equilibrium. Although this relation is obtained in 3D, we assume that it is also valid for the 2D distributions. By converting the axis ratio of the gas distribution into the dark matter distribution using the results in Fig. 3 of Lee & Suto (2003), we infer 2D axis ratios for dark matter haloes of 0.6 ± 0.1 , in good agreement with our measurements (0.69 for groups with halo masses $10^{14} - 10^{15} h^{-1} M_\odot$).

3.4 Dependence of halo shape on the color of central galaxies

The color-magnitude relation of galaxies is found to have a bi-modal distribution, consisting of a red ‘sequence’ and a blue ‘cloud’ (e.g. Baldry et al. 2004; Li et al. 2006). In this subsection we test whether haloes that host red or blue central galaxies have different shapes (the motivation behind this will become clear in §4). Following Li et al. (2006) and

Yang et al. (2008) we separate galaxies into red and blue population using the following dividing curve,

$$^{0.1}(g-r)_0 = 1.022 - 0.0651 * M_{r,23} - 0.00311 * M_{r,23}^2, \quad (8)$$

where $M_{r,23} = ^{0.1}M_r - 5 \log h + 23$, and $^{0.1}M_r - 5 \log h$ is the absolute magnitude $K + E$ corrected to $z = 0.1$ using the method described in Blanton et al. (2003). We define galaxies with $^{0.1}(g-r) \geq ^{0.1}(g-r)_0$ as red galaxies and the rest as blue galaxies. Here $^{0.1}(g-r)$ is the color in the SDSS g and r bands $K + E$ corrected to $z = 0.1$. In Fig. 5, we compare the ellipticity distribution for groups with red and blue central galaxies. The results indicate that there is no significant difference between the shape of groups with blue or red central galaxies.

4 ALIGNMENT BETWEEN CENTRAL GALAXIES AND DARK MATTER HALOES

4.1 Quantifying the alignment

In order to quantify the distribution of satellite galaxies in groups relative to the orientations of their central galaxies we follow Brainerd (2005) and compute the distribution function, $P(\theta)$, where θ is the angle between the major axis of the central group galaxy and the direction of a satellite

Figure 5. Probability distribution of the ellipticity for groups with different central galaxies: red (solid line) v.s. blue (dotted line).

relative to the central galaxy. The angle θ is constrained in the range $0^\circ \leq \theta \leq 90^\circ$, where $\theta = 0^\circ(90^\circ)$ implies that the satellite lies along the major (minor) axis of the central galaxy. The orientation of the central galaxy is based on the isophotal position angle in the r band, as given in the SDSS-DR4 (Adelman-McCarthy et al. 2006). We have checked the distribution of these position angles and found it to be isotropic.

For a given set of central and satellite galaxies, we first count the total number of central-satellite pairs, $N(\theta)$, for a number of bins in θ . Next, we construct 100 random samples in which we randomize the orientations of all central galaxies, and compute $\langle N_R(\theta) \rangle$, the average number of central-satellite pairs as function of θ . Note that this ensures that the random samples have exactly the same selection effects as the real sample, so that any significant difference between $N(\theta)$ and $N_R(\theta)$ reflects a genuine alignment between the orientations of the central galaxies and the distributions of their corresponding satellite galaxies.

To quantify the strength of any possible alignment we follow Y06 and define the distribution of normalized pair counts:

$$f_{\text{pairs}}(\theta) = \frac{N(\theta)}{\langle N_R(\theta) \rangle}. \quad (9)$$

Note that in the absence of any alignment, $f_{\text{pairs}}(\theta) = 1$, while $f_{\text{pairs}}(\theta) > 1$ at small θ implies a satellite distribution with a preferred alignment along the major axis of their central galaxy. We use $\sigma_R(\theta)/\langle N_R(\theta) \rangle$, where σ_R is the standard deviation of $N_R(\theta)$ obtained from the 100 random samples, to assess the significance of the deviation of $f_{\text{pairs}}(\theta)$ from unity. In addition to this normalized pair count, we also compute the average angle $\langle \theta \rangle$. In the absence of any alignment $\langle \theta \rangle = 45^\circ$, however, $\langle \theta \rangle = 45^\circ$ does not mean an isotropic distribution. Major and minor axis alignments are characterized by $\langle \theta \rangle < 45^\circ$ and $\langle \theta \rangle > 45^\circ$, respectively. The significance of any alignment can be expressed in terms of σ_θ , the variance in $\langle \theta \rangle_R$, which is obtained from the 100 random samples.

Fig. 6 shows $f_{\text{pairs}}(\theta)$ for all central-satellite pairs (solid line) in our SDSS group catalogue. Clearly $f_{\text{pairs}}(\theta) > 1$

Figure 6. The normalized probability distribution, $f_{\text{pairs}}(\theta)$, of the angle θ between the major axis of the central galaxy and the direction connecting the satellite galaxy and the central galaxy. Results are measured for groups with at least two members (solid line) and four members (dotted line).

for small θ , indicating that satellite galaxies are distributed preferentially along the major axis of their central galaxy. This is also evident from the fact that $\langle \theta \rangle = 42.46^\circ \pm 0.12^\circ$, which deviates from the case of no alignment (i.e., $\langle \theta \rangle = 45^\circ$) by almost 21σ ! For comparison, using the a group catalogue constructed from the SDSS DR2 data by Weinmann et al. (2006), similar to that used here, Y06 found $\langle \theta \rangle = 42.2^\circ \pm 0.2^\circ$, in excellent agreement with the results presented here. Note, though, that the statistical error presented here is much smaller, due to the larger group catalogue used. The existence of alignment owns in part to the non-spherical distribution of the satellite galaxies in dark matter haloes (e.g., Zentner et al. 2005; Kang et al. 2005, 2007; Libeskind et al. 2005; AB06), which has been used in the previous section to probe the overall shapes of the dark matter mass distribution. For comparison, the dotted lines in Fig. 6 show $f_{\text{pairs}}(\theta)$ for groups with at least four members. The resulting alignment signal is slightly stronger than for the full sample (which includes all central-satellite pairs in groups with at least two members). This is consistent with the fact that (i) groups with more satellites are more massive and (ii) more massive groups are less spherical (see also §4.1.2 below).

4.1.1 Dependence on galaxy color

In order to study how the alignment depends on various properties of the central and satellite galaxies, we follow Y06 and divide our sample of central-satellite pairs into different subsamples. The upper panels of Fig. 7 show the alignment signals obtained for blue and red satellites, while the lower panels show the results for blue and red centrals. As one can see, there is a strong dependence on the colors of both the centrals and satellites. In particular, groups with red centrals and red satellites show a stronger alignment than those with blue centrals and blue satellites, in good agreement with previous studies (Y06; Azzaro et al. 2007; Agustsson & Brainerd 2007). As pointed out by K07, groups with blue centrals tend to have slightly more interlopers, which

Figure 7. Same as Fig. 6, but for different subsamples of central-satellite pairs, separated according to the $^{0.1}(g-r)$ colors either for satellite galaxies (upper two panels) and for central galaxies (lower two panels).

Figure 8. Same as Fig. 7, except that here we split the sample according to different combinations of the colors for *both* central and the satellite galaxies, as indicated.

may cause an artefactual reduction of their measured alignment. However, even after this is corrected for, groups with blue centrals still show a weak alignment.

In Fig. 8 we show the alignment, $f_{\text{pairs}}(\theta)$, for the four color combinations of centrals and satellites. As one can see, pairs between blue centrals and blue satellites do not show any alignment, while pairs between red centrals and red satellites show the strongest alignment. Pairs between red centrals and blue satellites and pairs between blue centrals and red satellites show alignment with intermediate strength. All these findings are in excellent agreement with, and more significant than, those obtained in Y06.

4.1.2 Dependence on halo mass

Fig. 9 shows the alignment measure for groups of different halo masses. From the upper panels one can see that the alignment is stronger for more massive groups. We also examine the mass dependence of the alignment separately for

Figure 9. Similar to Fig. 6, but for central-satellite pairs in haloes of different masses as indicated on top of the panels. Results are shown separately for all, red and blue central galaxies in the upper, middle and lower panels.

groups with blue and red centrals, the results of which are shown in the middle and lower panels of Fig. 9, respectively. The alignment is quite different for blue and red centrals. For all halo masses probed here, red centrals reveal a much stronger alignment with their satellite galaxies than blue centrals. In fact, except for the most massive haloes with $14 \leq \log M / h^{-1} M_{\odot} \leq 15$, we find no significant alignment signal of satellites with blue centrals. These results are again in good agreement with the findings of Y06 based on galaxy groups in the SDSS DR2 (see also Agustsson & Brainerd 2007).

4.2 The alignment of central galaxies with their host haloes

As shown above, central galaxies are aligned with the distribution of their satellite galaxies, and different systems show different levels of alignment. To produce such an alignment signal requires that (i) dark matter haloes are elongated, (ii) satellite galaxies trace the dark matter, at least to some extent, and (iii) the orientation of the central galaxy is correlated with the orientation of its dark matter halo. Now that we have obtained constraints on both the shapes of dark matter haloes, we can use the observed alignment signals to constrain the correlation between the orientations of central galaxies and their dark matter haloes.

Previously, such correlations have been constrained using galaxy catalogues constructed from semi-analytical models (SAM) for galaxy formation (see AB06 and K07). In K07, the satellite distributions are modelled using the locations of subhaloes (which are thought to host the satellite galaxies) inside larger dark matter haloes in a numerical simulation. In general, subhaloes are found to be accurate tracers of the shapes of the dark matter distributions of their host haloes. However, since the SAM do not predict the orientations of the central galaxies, a number of simple assumptions have been made so far, where the minor axis of the central is perfectly aligned with (i) the major axis of the inertia tensor of the host halo, (ii) the minor axis of the inertia tensor of the host halo, (iii) the intermediate axis of the inertia tensor of

Figure 10. The alignment signal $f_{\text{pairs}}(\theta)$ obtained by consider the misalignment-angle between the major axis of the dark matter halo and the major axis of the central group galaxy. Upper panels: the alignment signals by assuming that the direction of central galaxy is same as the direction of the projected major axis of the dark matter halo (dashed line), comparing to the observed alignment signal (solid line). Lower panels: The comparisons between the observed alignment signal (solid line) and the best fitting alignment signal by considering a misalignment between the projected major axis of the dark matter halo and the major axis of the central galaxy (dashed line).

the host halo, or (iv) the angular momentum vector of the host halo. Both AB06 (using the alignment signal measured from isolated host-satellite systems) and K07 (using central-satellite pairs in galaxy groups) found that model (i) predicts an alignment signal that is much too strong compared with the data, model (ii) predicts a strong Holmberg effect, contrary to what is seen, and model (iii) predicts almost no alignment. Only model (iv) results in alignment signals that are in agreement with observations. Although this does not give definite proof that the minor axis of the central galaxy is perfectly aligned with the angular momentum vector of the halo, it does provide a possible understanding for the origin of a correlation between the orientation a central galaxy and that of its host halo.

However, it is important to keep in mind that the SAM not necessarily predict the correct spatial distributions of satellite galaxies. Therefore, in this paper we focus on what can be inferred from the data alone. In particular, we try to *infer*, based purely on the data presented here, to what extent the *projected* orientations of central galaxies are aligned with those of their dark matter haloes. Similar to what we have done to extract the three-dimensional and two-dimensional axis ratios in Section 3, we compare the data to Monte Carlo simulations. We start from the groups with at least four members, and assume that the projected orientations of the central galaxies are perfectly aligned with the orientation of the projected satellite distribution. Next, using a Monte Carlo method, we distribute the satellite galaxies according to the projected two-dimensional axis ratios listed in the fourth column of Table 1 for the group sample with $N \geq 4$. Finally, we measure the various alignment signals for this Monte Carlo simulation using the same method as described above. The upper panels of Fig. 10 show the alignment signals thus obtained (open symbols) for groups

of different masses, as indicated at the top of each panel. For comparison, we also plot the data as asterisks. Clearly, this model predicts an alignment signal that is stronger than observed, especially for the more massive groups.

We can suppress the strength of the alignment signals in the model by taking scatter (i.e., ‘random’ deviations from perfect alignment) into account. To that extent we assume that the misalignment angle between the projected orientation of the central galaxy and the major axis of its host halo can be described by a Gaussian distribution:

$$p(\theta_{\text{mis}}) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{\theta_{\text{mis}}^2}{2\sigma^2}\right), \quad (10)$$

with σ the standard deviation of the distribution. Note that this distribution for the misalignment angle θ_{mis} is symmetric and centered around zero.

Using such a Gaussian distribution, we fit the various alignment signals obtained from our SDSS group catalogue, treating σ as a free parameter in each separate case. Here again we use the minimum χ^2 fit, similar to Eq. 7 but for the angular distribution of central-satellite pairs (Eq. 9). The parameter σ is constrained in the range $0^\circ - 90^\circ$, and on the regular 900 grids. For each σ , the misalignment angles θ_{mis} are generated according to the Gaussian distributions. We measure the alignment signals in Monte Carlo mock samples in the same way as the observations, and obtain χ^2 values on 900 grids. The best-fit parameter σ can be obtained from the grid which has the minimum χ^2 value. As an illustration, in the lower panels of Fig. 10 we compare the alignment signals obtained from the data (asterisks) with those obtained from the Monte Carlo simulations including the best-fit Gaussian distribution of misalignment angles (open symbols). Clearly, the observed results can be well reproduced by such a model. Table 3 lists the best-fit values of σ thus obtained, for a variety of cases that are shown in Figs. 6 - 9. To better describe these statistical values, 68.3% confidence levels are also given following each best fit σ . Here the confidence levels are obtained from the grids with $\chi^2 = \chi_{\text{min}}^2 + 1.0$. Clearly, the amount of scatter in the misalignment angle depends strongly on the group mass and on the color of the central galaxy. For the entire sample as a whole we obtain $\sigma \sim 23^\circ$, while groups with red centrals, on average, have smaller misalignment angles than those with blue centrals. Owing to the nearly spherical shapes of dark matter haloes with $12.0 < \log[M/h^{-1}M_\odot] \leq 13.0$, the misalignment angle could not be meaningfully constrained in these cases.

In a recent study, K07 found that if the minor axis of the central galaxy and the angular momentum vector of the dark matter halo is in perfect alignment, most of the observational satellite-central alignment signals can be automatically reproduced. On the other hand, any processes that can introduce an average misalignment $\sim 40^\circ$ between the minor axes of central galaxy and host dark matter halo can also explain the observed alignment signals. Using high resolution numerical simulations, Bailin & Steinmetz (2005) found that the angular momentum vectors tend to align with the minor axes of the dark matter halo with a mean misalignment of $\sim 25^\circ$ at small radii and of $\sim 40^\circ$ at the halo virial radius. Here to be able to compare with our findings, as an experiment, we input misalignment angles (with an average $\sim 40^\circ$ and some scatters) between the minor axes of the dark matter haloes and the central galaxies. By randomly project

Table 2. Best fitting parameters for the deviation angle between the orientation of the central galaxy and the dark matter halo.

Subsample	σ (degree)
all ^a	$23.3^{+0.1}_{-0.3}$

red cen. (M45)	$25.7^{+0.3}_{-0.1}$
blue cen. (M23)	—
blue cen. (M34)	$64.8^{+0.1}_{-0.5}$
blue cen. (M45)	$27.2^{+0.1}_{-0.1}$
all (M23)	—
all (M34)	$23.3^{+0.2}_{-0.3}$
all (M45)	$30.2^{+0.1}_{-0.2}$

^a all means all central galaxies

^b blue cen. and red cen. denote blue centrals and red centrals, respectively.

^c blue sat. and red sat. denote blue satellites and red satellites, respectively.

^d M23 means that the halo masses are in the range $12 < \log[M/h^{-1}M_{\odot}] \leq 13$. Note that in M23, the alignment signals for the perfect alignment are already as weak as the observed ones, and so no misalignment angle is introduced.

the 3D shapes of the dark matter haloes and central galaxies, we measure the distribution of the angles between the *projected major* axes of the dark matter halos and central galaxies, if modelled with an Gaussian distribution, which roughly corresponds to $\sigma \sim 22^\circ$. Thus our finding are in remarkably good agreement with K07 and Bailin & Steinmetz (2005).

5 SUMMARY AND DISCUSSION

Using the large galaxy group catalogues constructed from the SDSS Data Release 4 (DR4) by Yang et al. (2007), we have investigated the shapes of their host dark matter haloes, and the correlation between the orientations of the central galaxies and those of their host haloes. In particular, we obtained the two-dimensional and three-dimensional axis ratios of galaxy groups by comparing the observed, projected ellipticity distributions of satellite galaxies with those of Monte Carlo simulations, and we determined the probability distributions for the angles between the major axis of central galaxies and the lines connecting the centrals with their satellites. The main results of this paper are summarized as follows.

(i) Under the assumption that the spatial distribution of satellite galaxies traces the shapes of the underlying dark matter haloes we find that the projected ellipticity distribu-

tions are slightly better fit with the triaxial models of JS02 than with simple, spherical NFW models.

(ii) The shapes of dark matter haloes depend strongly on their mass, with more massive haloes being more elongated. Haloes with masses in the range $12 < \log[M/h^{-1}M_{\odot}] \leq 13$ are nearly spherical, while more massive haloes with $14 < \log[M/h^{-1}M_{\odot}] \leq 15$ are more prolate.

(iii) There is no significant difference between the shapes of haloes with red central galaxies and those with blue central galaxies.

(iv) Satellites are preferentially distributed along the major axes of their central galaxies. The strength of this alignment depends strongly on halo mass and on the colors of both central and satellite galaxies. The alignment is strongest between red centrals and red satellites, while blue centrals show almost no alignment at all. More massive groups show a stronger alignment than less massive groups.

(v) The observed alignment can be reproduced if the projected orientation of central galaxies is aligned with that of the projected mass distribution of its halo. However, the alignment is not perfect. The data can be reproduced under the assumption that the misalignment angle follows a Gaussian distribution around zero, and with a standard deviation of ~ 23 degrees. Because of (ii) and (iii) and (iv), groups with blue centrals have, on average, a larger misalignment angle than those with red centrals.

Our findings regarding the shapes of the galaxy groups are in qualitative agreement with those of P06, and Plionis et al. (2004). However, there are quantitative difference, especially for small haloes. We find that small haloes are almost spherical, and the axis ratios (major-to-minor) in our measurements are much smaller than their measurements. Note that we have used Monte Carlo simulations to infer the shapes of dark matter haloes, which avoids the impact of selection effects, while in Plionis et al. (2004) the axis ratios are directly measured from the distribution of member galaxies. Although they found that poor groups are more elongated than rich ones, they cautioned that their results may be significantly affected by discreteness effects (see also Plionis et al. 2006). Numerical simulations (e.g. Kasun & Evrard 2005; Allgood et al. 2006) have shown that the small haloes are more spherical than massive haloes, in good agreement with our findings here.

The alignment signals presented here are in good agreement with those obtained by Y06 using a similar, but smaller group catalogue constructed from the SDSS DR2, and with other studies (Brainerd 2005; Agustsson & Brainerd 2006a, 2007; Donoso, O’Mill & Lambas 2006; Faltenbacher et al. 2007a; Azzaro et al. 2007). Contrary to the previous studies by AB06 and K07, our analysis of the implications for the correlation between the orientation of the central galaxies and that of its halo are based purely on the data presented here, and therefore does not depend on any galaxy formation models or numerical simulations. Nevertheless, tests show that their models of the perfect alignment between the minor axis of the central galaxy and angular momentum vector of dark matter halo are in good agreement with our direct measurement of the projected misalignment angles.
